

# Xilinx Stacked Silicon Interconnect Technology Delivers Breakthrough FPGA Capacity, Bandwidth, and Power Efficiency

By: Kirk Saban

The programmable imperative—the critical need to achieve more with less, to reduce risks wherever possible, and to quickly create differentiated products using programmable hardware design platforms—is driving the search for FPGA-based solutions that provide the capacity, lower power, and higher bandwidth with which users can create the system-level functionality currently delivered by ASICs and ASSPs.

Xilinx has developed an innovative approach for designing and manufacturing FPGAs that address two key requirements of the programmable imperative. Stacked silicon interconnect (SSI) technology is the foundation of a new generation of FPGAs that break through the limitations of Moore's law and deliver the capabilities to satisfy the most demanding design requirements. It also enables Xilinx to reduce the time required to deliver the largest FPGAs in the quantities needed to satisfy end-customer volume production requirements. This white paper explores the technical and economic challenges that led Xilinx to develop SSI technology and innovations that make it possible.

### Introduction

As the role of the FPGA becomes more dominant in system design, the designs grow larger and more complex, demanding higher logic capacity and more on-chip resources. To date, FPGAs have depended predominantly on Moore's Law to respond to this need, delivering nearly twice the logic capacity with each new process generation. However, keeping pace with today's high-end market demands requires more than Moore's Law increases can provide.

The most aggressive adopters of FPGA technology are eager to employ the highest capacity, highest bandwidth devices of each new FPGA generation. However, the challenges of building large FPGAs early in the product life cycle can limit the ability to supply the volumes of devices these customers require for their production runs. That is because the circuitry overhead that enables reprogrammable technology negatively affects the manufacturability (and therefore, the supply) of the largest FPGAs. At the early stages of a new process node, when defect densities are high, die yield declines dramatically as die size increases. As the fabrication process matures, defect density falls and the manufacturability of large die increases significantly.

Thus, while the largest FPGAs are in short supply at product introduction, over time they eventually become available in quantities that support end-customer volume requirements. In response to the programmable imperative, a few leading-edge customers have challenged Xilinx to find a way to support their volume production requirements with the largest FPGAs as soon as possible after product introduction.

For example, the telecommunications market needs FPGAs that incorporate dozens of serial transceivers with increased interconnect logic and block RAM for advanced data processing and traffic management, while enabling use within current form factors and power footprints. To reap first-mover advantage, the equipment makers want to ramp up manufacturing of their new products as rapidly as possible.

Xilinx has responded to these requirements with an innovative approach for building FPGAs that offer bandwidth and capacity equaling or exceeding that of the largest possible FPGA die with the manufacturing and time-to-market advantages of smaller die to accelerate volume production. These benefits are enabled by SSI technology, which uses passive silicon interposers with microbumps and through-silicon vias (TSVs) to combine multiple highly manufacturable FPGA die slices, referred to as super logic regions (SLRs), in a single package.

#### The Challenges of Interconnecting Multiple FPGAs

SSI technology solves the challenges that had previously obstructed attempts to combine the interconnect logic of two or more FPGAs to create a larger, "virtual FPGA" for implementing a complex design:

- The amount of available I/O is insufficient for connecting the complex networks of signals that must pass between FPGAs in a partitioned design and as well as connecting the FPGAs to the rest of the system.
- The latency of signals passing between FPGAs limits performance.
- Using standard device I/O to create logical connections between multiple FPGAs increases power consumption.

#### Key Challenge: Limited Connectivity and Bandwidth

System-on-chip (SoC) designs comprise millions of gates connected by complex networks of wires in the form of multiple buses, complicated clock distribution networks, and multitudes of control signals. Successfully partitioning an SoC design across multiple FPGAs requires an abundance of I/Os to implement the nets spanning the gap between FPGAs. With SoC designs including buses as wide as 1,024 bits, even when targeting the highest available pin count FPGA packages, engineers must use data buffering and other design optimizations that are less efficient for implementing the thousands of one-to-one connections needed for high-performance buses and other critical paths.

Packaging technology is one of the key factors to this I/O limitation. The most advanced packages currently offer approximately 1,200 I/O pins, far short of the total number of I/Os required.

At the die level, I/O technology presents another limitation because I/O resources do not scale at the same pace as interconnect logic resources with each new process node. When compared to transistors used to build the programmable logic resources in the heart of the FPGA, the transistors comprising device I/O structures must be much larger to deliver the currents and withstand the voltages required for chip-to-chip I/O standards. Thus, increasing the number of standard I/Os on a die is not a viable solution for providing the connections for combining multiple FPGA die.

#### Key Challenge: Excessive Latency

Increased latency is another challenge with the multiple FPGA approach. Standard device I/Os impose pin-to-pin delays that degrade the overall circuit performance for designs that span multiple FPGAs. Moreover, using time-domain multiplexing (TDM) on standard I/Os to increase the virtual pin count by running multiple signals on each I/O imposes even greater latencies that can slow I/O speeds down by a factor of 4X–32X or more. These reduced speeds are often acceptable for ASIC prototyping and emulation, but are often too slow for end-product application.

#### Key Challenge: Power Penalty

TDM approaches also result in higher power consumption. When used to drive hundreds of package-to-package connections across PCB traces between multiple FPGAs, standard device I/O pins carry a heavy power penalty compared to connecting logic nets on a monolithic die.

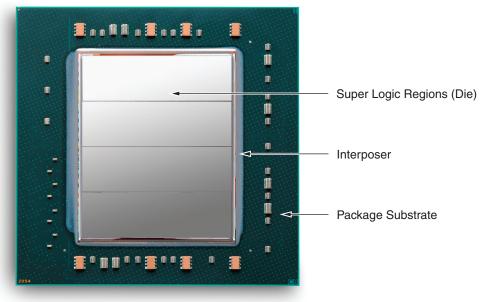

Similarly, multichip module (MCM) technology offers potential form-factor reduction benefits for integrating multiple FPGA die in a single package. The MCM approach, however, still suffers from the same restrictions of limited I/O count as well as undesirable latency and power consumption characteristics.

## Xilinx SSI Technology

To overcome these limitations and roadblocks, Xilinx has developed a new approach for building production volumes of high-capacity FPGAs. The new solution enables high-bandwidth connectivity between multiple die by providing a much greater number of connections. It also imposes much lower latency and consumes dramatically lower power than the multiple FPGA approach, while enabling the integration of massive quantities of interconnect logic and on-chip resources within a single package.

Within the density range of an FPGA family, the medium-density devices represent the "sweet spot." That is, compared to the previous generation, they offer significantly greater capacity and bandwidth—on a die size that can be delivered earlier in the FPGA product life cycle than the largest devices in the same family. Thus, by combining several of these die in a single device, it is feasible to match or exceed the capacity and bandwidth offered by the largest monolithic devices, but with the manufacturing and time-to-volume advantages of smaller die.

Xilinx arrived at such a solution by applying several proven technologies in an innovative way. By combining TSV and microbump technology with its innovative ASMBL™ architecture, Xilinx is building a new class of FPGAs that delivers the capacity, performance, capabilities, and power characteristics required to address the programmable imperative. Xilinx SSI technology combines multiple FPGA SLRs via a passive silicon interposer. The interposer provides tens of thousands of SLR to SLR connections to enable ultra-high interconnect bandwidth with far lower power consumption and one fifth the latency of standard I/Os. Figure 1 shows the top view of the die stack-up with four FPGA die slices, silicon interposer, and package substrate.

Figure 1: Virtex®-7 2000T FPGA Enabled by SSI Technology

Originally developed for use in a variety of die-stacking design methodologies, silicon interposers provide modular design flexibility and high-performance integration suitable for a wide range of applications. The silicon interposer acts as a sort of micro-circuit board in silicon on which multiple die are set side by side and interconnected. SSI technology avoids the power and reliability issues that can result from stacking multiple FPGA dies on top of each other. Compared to organic or ceramic substrates, silicon interposers offer far finer interconnect geometries (approximately 20X denser wire pitch) to provide device-scale interconnect hierarchy that enables more than 10,000 die-to-die connections.

#### Creating FPGA Die Slices with Microbumps for Stacked Silicon Integration

The foundation of Xilinx SSI technology is the company's proprietary ASMBL architecture, a modular structure comprising Xilinx FPGA building blocks in the form of tiles that implement key functionality such as configurable logic blocks (CLBs), block RAM, DSP slices, SelectIO™ interfaces, and serial transceivers. Xilinx engineers organize the blocks in columns of each type of tile and then combine the columns to create an FPGA. By varying the height and arrangement of columns, the Xilinx engineers can create an assortment of FPGAs with different amounts and mixes of logic, memory, DSP, and I/O resources (Figure 2). The FPGA contains additional blocks for generating clock signals and for programming the SRAM cells with the bitstream data that configures the device to implement the end user's desired functionality.

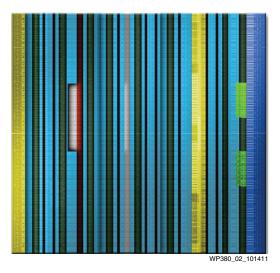

Figure 2: Representation of an FPGA Built with ASMBL Architecture

Starting with the basic ASMBL architectural construct, Xilinx has introduced three key modifications that enable stacked silicon integration (see Figure 3). First, each die slice receives its own clocking and configuration circuitry. Then the routing architecture is modified to enable direct connections through the passivation on the surface of the die to routing resources within the FPGA's logic array, bypassing the traditional parallel and serial I/O circuits. Finally, each SLR undergoes additional processing steps to fabricate microbumps that attach the die to the silicon substrate. It is this innovation that enables connections in far greater numbers, with much lower latency, and much less power consumption than is possible using traditional I/Os (100X the SLR-to-SLR connectivity bandwidth per watt versus standard I/Os).

Figure 3: FPGA SLR (Die) Optimized for SSI Technology

#### Silicon Interposer with TSV

The passive silicon interposer interconnects the multiple FPGA SLRs together. It is built on a low-risk, high-yield 65 nm process and provides four layers of metallization for building the tens of thousands of traces that connect the logic regions of multiple FPGA die (Figure 4).

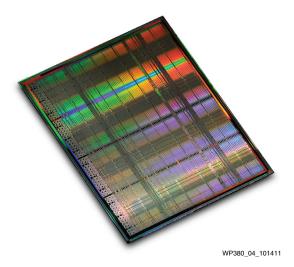

Figure 4: Passive Silicon Interposer

Figure 5 illustrates the concept of an "X-ray view" of the assembled die stack. It contains a stack-up of four FPGA SLRs mounted side by side on a passive silicon interposer (bottom view). The interposer is shown as transparent to enable a view of the FPGA SLRs connected by traces on the silicon interposer (not to scale).

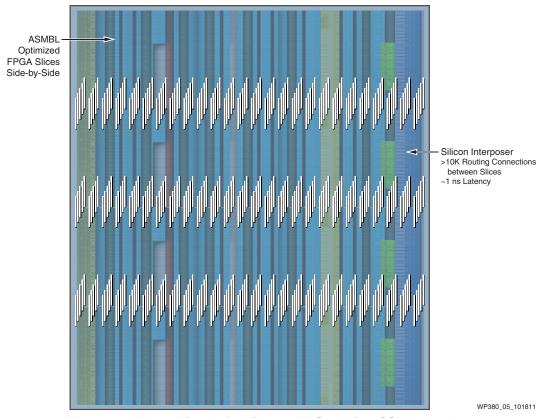

Figure 5: "X-ray View" of a Virtex-7 FPGA Using SSI Technology

The TSVs combined with controlled-collapse chip connection (C4) solder bumps enable Xilinx to mount the FPGA/interposer stack-up on a high-performance package substrate using flip-chip assembly techniques (Figure 6). The coarse-pitch TSVs provide the connections between the package and the FPGA for the parallel and serial I/O, power/ground, clocking, configuration signals, etc.

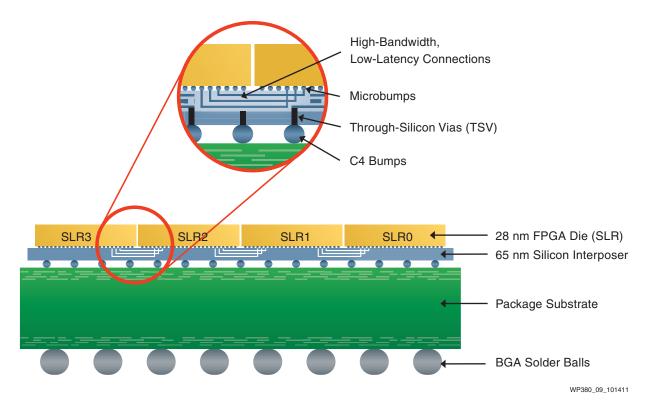

Figure 6: Package Side Cutaway View

Comprising numerous patent-pending innovations, this SSI technology provides multi-Terabit-per-second die-to-die bandwidth through more than 10,000 device-scale connections—enough for the most complex multi-die designs. Xilinx is using this new technology to enable several members of the Virtex-7 FPGA family, as shown in Table 1.

Table 1: Virtex-7 FPGAs

	Virtex-7 FPGAs						
Virtex-7 T	7V585T	7V1500T	7V2000T				
Virtex-7 XT	7VX330T	7VX415T	7VX485T	7VX550T	7VX690T	7VX980T	7VX1140T
Virtex-7 HT	7VH290T	7VH580T	7VH870T				

#### Notes:

1. The shaded devices utilize SSI technology.

The SSI-enabled devices shown in Table 1 offer unprecedented capabilities including up to: two million logic cells; 68 Mb of block RAM; 5,335 GMACS of DSP performance; 1,200 SelectIO pins supporting 1.6 Gb/s LVDS parallel interfaces; and 96 serial transceivers delivering 2,938 Gb/s aggregate bidirectional bandwidth.

## FPGA Design with SSI Technology

One of the more substantial advantages afforded by Xilinx FPGAs with SSI technology is the ability to treat it like a monolithic device. This is extremely important because partitioning a large design across multiple FPGAs presents a number of complicated design challenges that monolithic implementations avoid entirely.

The typical steps in a monolithic FPGA design flow include:

- Create a high-level description
- Synthesize into an RTL description that matches the hardware resources
- Perform physical place and route
- Estimate timing and adjust design for timing closure
- Generate a bitstream to program FPGAs

When working with multiple FPGAs, the designer (or design team) must partition the netlist across the FPGAs. Working with multiple netlists means opening and managing multiple projects, each with its own design file, IP libraries, constraint files, packaging information, etc.

Timing closure for multiple FPGA designs can also be extremely challenging. Calculating and accommodating propagation delays through the board to the other FPGAs poses new and complex problems. Likewise, debugging a design through multiple partial netlists in multiple FPGAs can be extremely complicated and difficult.

In contrast, when using FPGAs with SSI technology, the designer creates and manages a single design project; SSI technology routing is transparent to the user. The user performs a single design bring-up and debug with a standard timing closure flow.

## **Applications**

Xilinx Virtex-7 FPGAs with SSI technology break through the limitations of monolithic FPGAs, extending their value in some of the most demanding applications. For example, these devices are perfect for use in ASIC prototyping and can serve as pre-production and/or initial-production ASIC alternatives. In next-generation telecom systems, devices with dozens of serial transceivers enable flexible, single-FPGA solutions, such as a 300G protocol bridging, or a multiplexing transponder implementation that can replace multiple ASSPs and reduce power by 50%. They also enable flexible, scalable, customized high performance computing solutions for scientific, oil and gas, financial, aerospace and defense, communications, networking, and life science applications. The parallelism inherent in the FPGA architecture is ideal for high-throughput processing and software acceleration. Support for a multitude of high-speed parallel and serial connectivity standards enables the convergence of compute and communications systems. In Aerospace and Defense, high transceiver count and thousands of DSP processing elements provided by FPGAs with SSI technology enable advanced RADAR implementations.

## SSI Technology - Concept to Reality

The development strategy Xilinx employed in the creation of SSI technology began with extensive modeling and the subsequent creation of a series of test devices, or test vehicles, used for design enablement, manufacturability, and reliability validation.

These test vehicles and stress simulation models showed an additional advantage of stacked silicon technology. The silicon interposer functions as a buffer that reduces low-K dielectric stress and improves C4 bump reliability, compared to monolithic solutions.

Extensive simulations and investigations of the thermal impact of the die stack showed that thermal performance of devices with SSI technology is comparable to that of monolithic devices.

The culmination of nearly six years of extensive research and development was realized in September 2011 when Xilinx shipped the world's highest capacity FPGA, the Virtex-7 2000T device, enabled by SSI technology. Xilinx has a robust supply chain in place to mass produce FPGAs with SSI technology. TSMC, Amkor, and Ibiden contribute their combined resources and expertise for fabricating 28 nm FPGAs and 65 nm silicon interposers, interconnect layers, microbumps, C4 balls, and package substrates as well as performing wafer thinning, die separation, chip-on-chip (CoC) attach, and package assembly.

## Summary

As the only FPGA manufacturer to use SSI technology to create super high capacity FPGAs with unmatched die-to-die bandwidth, Xilinx is breaking important new ground in the system-level integration arena. SSI technology enables Xilinx to deliver the highest logic density, bandwidth, and on-chip resources with the fastest ramp to volume production at every process node.

Customers will find these FPGAs with SSI technology significantly easier to design with than multiple FPGAs, with flexible tool flows that provide complete design tools for ease of use, yet allow designer interaction for achieving even higher performance.

Xilinx is now shipping the world's highest capacity FPGA, the Virtex-7 2000T device, enabled by SSI technology. For more information, visit <a href="https://www.xilinx.com/7">www.xilinx.com/7</a>.

## **Revision History**

The following table shows the revision history for this document:

Date	Version	Description of Revisions
10/27/10	1.0	Initial Xilinx release.
10/21/11	1.1	Updated Introduction. Updated Xilinx SSI Technology, including all figures. Added Table 1. Updated and interchanged Applications and SSI Technology - Concept to Reality. Updated Summary.
